#### **ABSTRACT**

Photographic parameters necessary for detailed interpretation of the *Ranger VII* pictures are listed for all of the A- and B-camera photographs and for selected P-camera photographs. Parameter accuracies and the method of data generation are discussed.

#### i. INTRODUCTION

This Report is intended as a supplementary tool for use in the analysis of the Ranger VII photographs of the Moon. As such, it contains a comprehensive list of the photographic parameters necessary for the detailed interpretation of the unrectified Ranger VII photographic atlases and film strips. The intent is to supply data in a form useful to the largest possible audience, including those who do not have photographic facilities at their disposal for rectification of the pictures. However, addi-

tional data are supplied for use in reproducing the object scene geometry.

A brief description of the method, assumptions, and accuracies which characterize the computation of the tabular photographic data is given. Each block of tabular data is identified by a tabular data number, the atlas frame number (if appropriate), and the frame number appearing on the original film recording of the mission.

## II. THE RANGER TELEVISION SYSTEM

The Ranger Block III spacecraft television system contained six cameras, divided into two separate channels designated F and P. The complete system has been discussed adequately in the Ranger atlas series; however, the camera characteristics are repeated here (Table 1).

The reticle pattern deposited on the faceplate of each vidicon differed for the F and P channels. The reticle patterns and the associated dimensions of the F-channel cameras are shown in Fig. 1. Because of the decreased target size used for the P cameras, the reticle pattern

Table 1. Camera characteristics

			Co	amera

<sup>\*</sup>The actual field of view in one direction was somewhat smaller than the given numbers because of the presence of a mask at the edge of the vidicon target which was used to determine scene black on each scan of the electron beam.

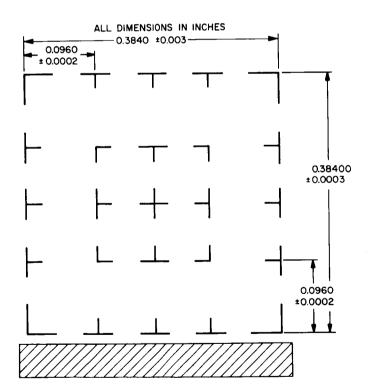

Fig. 1. Reticle dimensions for F-channel cameras

was designed differently. The pattern type and dimensions are shown in Fig. 2.

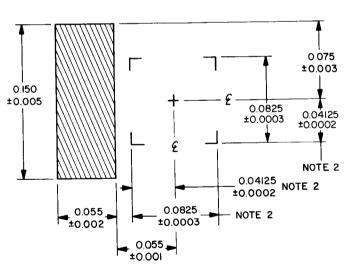

Fig. 2. Reticle dimensions for P-channel cameras

In some cases, it was necessary to use a vidicon tube with an F-type reticle pattern for a P camera. In these instances, only the center reticle is visible, as all other reticles fall outside the P-camera target area. This was the case for the Ranger VII P<sub>1</sub> camera.

## III. METHOD OF COMPUTATION OF SPACECRAFT-PHOTOGRAPH PARAMETERS

#### A. Computer Program Description

The photographic data contained in this Report were generated by a computer program which uses a hyperbolic approximation to the spacecraft trajectory near impact (Ref. 1). Knowledge of the attitude-sensor locations within the spacecraft and the sensor stimuli locations (Sun and Earth) in Moon-centered coordinates permitted computation of the spacecraft orientation. The oscillations and motion of the spacecraft as determined by the telemetry data were incorporated as a correction to the calculated orientation. Preflight calibration data were utilized to provide an initial determination of the camera system pointing direction in terms of spacecraft coordinates. The computer program spacecraft-camera model could then be used to compute the location of any picture point on the lunar surface in terms of lunar latitude-longitude coordinates.

For accurate photographic parameter computations, however, one cannot rely completely on preflight calibration data, and a verification or derivation of the camera parameters from the flight data is necessary. Among these camera parameters are camera cycle time, focal length, vidicon target dimensions, and true camera orientation within the spacecraft. With the knowledge of these parameters and the indicated spacecraft characteristics, the mapping from the Moon to the camera vidicon surface is then completely specified.

## **B.** Solution for Camera Parameters

The camera cycle time during actual flight could be verified by postflight examination of the magnetic tapes which recorded the data, along with an accurate 1-Mc time base signal. The postflight determinations of cycle time yielded values that deviated less than 0.01% from the design value; however, the postflight values were still used in the computations. Because of shutter stroke unknowns, the time at which the last picture was exposed could be determined no more accurately than  $\pm 0.002$  sec. This value may be of some consequence in the computations for the last picture parameters but certainly is of little significance for all other picture computations.

The preflight evaluation of the camera pointing directions within the spacecraft may not be representative of flight alignment for several reasons, among which are accuracy of original data, biases in the spacecraft sensor system, and launch vibrations. During the construction

of their series of Ranger lunar maps, the Aeronautical Chart and Information Center\* determined the latitude-longitude of the surface point covered by the central reticle from each camera at various times during the descent. These data were used by JPL to solve for the pointing direction of each camera that would best fit the observed data. All corrections were made by changing the pointing direction of the camera within the space-craft coordinate system. The magnitude of shift of the pointing directions as compared to the preflight values was about 0.5 deg. Note that this procedure does not separate misalignment effects due to attitude-sensor biases from camera misalignment, but does allow a combined correction for both types of errors.

Measurements from the film data showed a variation in the dimensions from reticle to reticle of up to 6%. These variations were found by comparing the distance between two reticles at different locations within the frame. The 6% variation applied, usually, to measurements made in widely separated areas of the frame and may have been due to local nonlinearities in scanning rate, or other camera electronic characteristics. It remained to be determined, however, whether these variations could be caused by inaccuracies in the placement of the reticle pattern on the vidicon surface and, finally, what the true focal length of each camera was. One could not, of course, solve independently for the reticle locations and focal lengths.

It was necessary to obtain additional data from the Aeronautical Chart and Information Center, this time in the form of surface points covered by the corner reticles of each camera during descent. Assumption of a focal length then made possible a best fit of the data to solve for the reticle location on the vidicon surface. It was found from these data that for a selected focal length, the reticles on the F cameras were within  $\pm 0.06$  mm (1  $\sigma$ ) of their theoretical location, with the mean value very close to the theoretical position. Because of the small fields of view on the P cameras, the data scatter was large, but the mean values of the solution for these reticles remained very close to the theoretical values. Even though the data scatter in all cases was larger than one would desire, the distributions were such as to give high confidence in the theoretical reticle positions. Thus, it was assumed that the reticles were deposited accurately.

<sup>\*</sup>United States Air Force, St. Louis, Missouri.

One should note that the readout linearity specification of the camera system was 2% of the picture dimension, which, in extreme cases, could give reticle-to-reticle variations on the order of 6 to 8%. In the course of the above solutions, the rotation of the individual cameras with respect to their theoretical locations was also obtained.

Assumption of the reticle locations as correct, then, made possible the solution of the camera focal distance from vidicon surface to lens exit pupil that best fit the observed data. Again, the data scatter was rather large for the narrow-angle cameras. The focal lengths of three lenses were measured prior to flight, and upon comparison of the preflight and empirically derived postflight values, it was found that they agreed quite well (see Table 2).

Table 2. Pre- and postflight focal-length determinations

Camera	Focal distance, mm determined from flight data	Preflight lens focal length, mm
A	25.64 ± 0.25	No measurements
В	74.62 ± 0.75	74.8
P <sub>1</sub>		74.8
P <sub>2</sub>	74.61 ± 4.5	74.65
$\mathbf{P}_3$	26.1 ±1.6	No measurement
P.	26.1 ± 1.6	No measurement

The data scatter is reflected in the tolerances listed for each focal distance. A nominal value for the Angenieux 25-mm lens was found to be 25.75 mm; unfortunately, individual measurements were not made on the *Ranger VII* A, P<sub>3</sub>, and P<sub>4</sub> lenses. Camera P<sub>1</sub> had no corner reticles, so that no postflight determination could be made.

## C. Assumptions and Accuracies

It has been assumed thus far that the trajectory can be approximated by a hyperbolic path (where the parameters are matched at impact with the true path), and that the theoretical reticle locations and the preflight measured focal lengths are correct. One other assumption made of necessity for the table generation was that of the Moon being a spherical body of radius equal to that chosen for the impact location.

The assumptions of the reticle locations and focal lengths were previously shown to have been reasonable, at least in comparison to the observable data scatter.

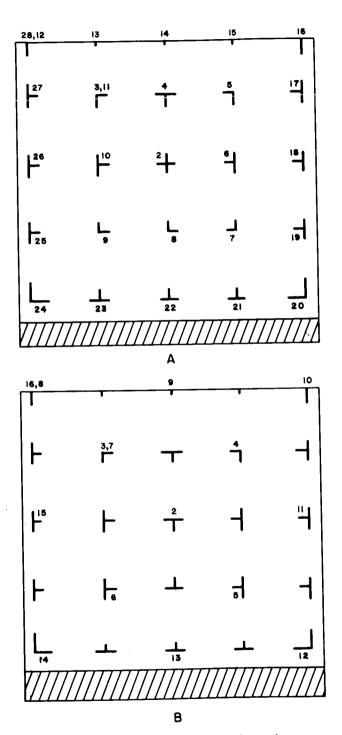

Fig. 3. Reticle number assignment, F-channel cameras

A comparison study of hyperbolic trajectory approximation to the integrated trajectory model has shown differences in altitude and time computations of less than 0.01% in the worst case. Finally, since all the computations were referenced to zero time at impact, and since the trajectories were steep with respect to the surface altitude variations, the assumption of a spherical Moon caused negligible errors.

Further, the impact point specified by the Aeronautical Chart and Information Center has been used. No uncertainties have been quoted for this point, but the latest orbit determination from tracking data gives a 1- $\sigma$  uncertainty ellipse of 0.10  $\times$  0.03 deg semimajor and -minor axis dimensions and a value of 0.10 deg magnitude difference from the ACIC point.

#### D. Location of Points Within Each Camera Frame

In determining the points within each frame for which to compute photographic parameters, it is logical to use the reticle locations. Sets of such points were chosen, and each reticle for which calculations were made was given a number which corresponded to a point number in the tabular data (see Figs. 3 and 4).

A special problem arose, however, where a reticle was only partially shown or where no corner reticles existed (as in the case of camera P<sub>1</sub>). For a partial reticle, the point was chosen at the intersection of the reticle and the edge of the frame. In the case of camera P<sub>1</sub>, points were selected at the two corners opposite the mask, and two other points were constructed as shown in Fig. 4.

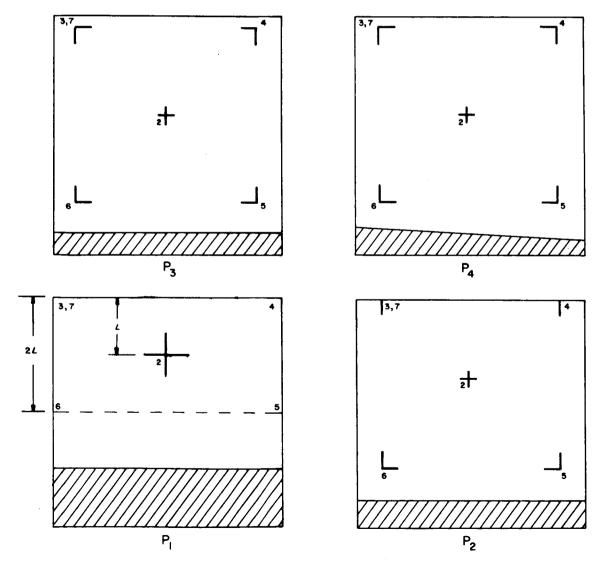

Fig. 4. Reticle number assignment, P-channel cameras

## IV. CONTENT OF TABLES

# A. Time- and Camera-Independent Parameters

The first page of the tabular data lists those quantities which are essentially time- and camera-independent for the duration of the picture-taking sequence. These quantities are particularly useful in reconstructing the object scene geometry on, say, a spherical globe (Fig. 5).

Subsolar point—the selenocentric latitude and longitude of the surface point intersected by the vector from the center of the Moon to the Sun.

Sub-Earth point—the selenocentric latitude and longitude of the surface point intersected by the vector from the center of the Moon to the center of Earth.

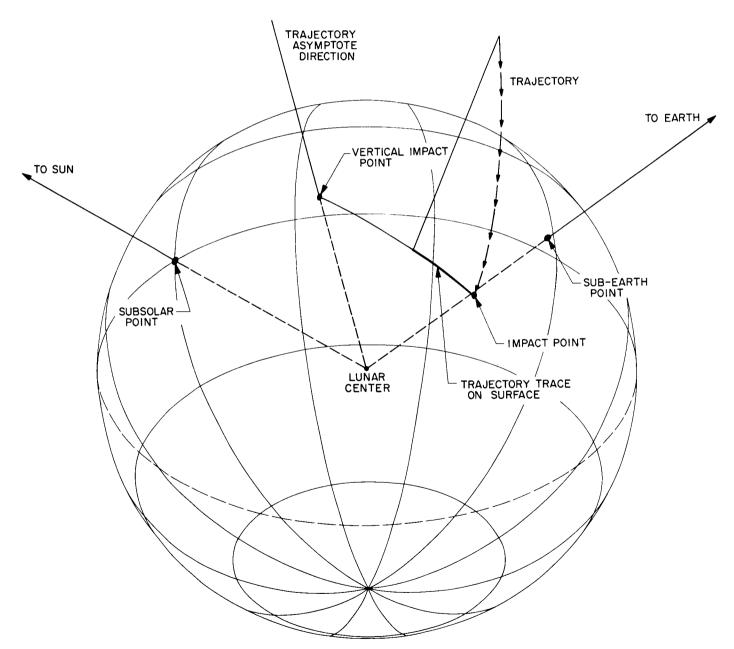

Fig. 5. Definition of subsolar, sub-Earth, and vertical impact points

Vertical impact point—the selenocentric latitude and longitude of the surface point intersected by the vector from the center of the Moon which describes the asymptotic direction of the spacecraft trajectory.

# B. Time- and Camera-Dependent Parameters

The main body of the tables consists of data blocks pertaining to each picture listed. Each data block is divided into three sub-blocks or subgroupings:

- 1. Frame identification
- 2. Trajectory data
- 3. Photo data

#### 1. Frame Identification

The parameters listed specify the photograph for which the data are generated.

TAB NO.—a number used to identify the table frames. The numbering starts at 1 and increases sequentially for each frame.

ATLAS NO.—the number that identifies, and is assigned to, those frames which appear in the Ranger atlas series. In the Ranger VII A and B atlases, the PHOTO NO. and ATLAS NO. are identical. In all other atlases, this is not the case.

POD NO.—the number of the frame as it appeared in the *primary original mission data*. In all cases, calculations are made for the last frame from each camera, so that the position of the frame in the overall sequence from camera initiation to impact is easily computed.

GMT-Greenwich Mean Time at which the photograph was exposed. This time is assumed to be known within  $\pm 0.005$  sec.

## 2. Trajectory Data

Trajectory data are those data necessary to describe the position and direction of movement of the spacecraft with respect to the Moon. The parameter headings are listed and explained below.

SEC TO IMPACT—the interval of time prior to spacecraft impact (seconds).

ALT—the spacecraft altitude above the surface of the Moon (kilometers). A spherical Moon of radius equal to that of the impact location is assumed.

LAT, LON—the subspacecraft point (degrees); i.e., the selenocentric latitude and longitude of the surface point intersected by the vector from the center of the Moon to the spacecraft.

R-the magnitude of the vector from the center of the Moon to the spacecraft (kilometers).

V-the spacecraft Moon-fixed velocity magnitude, i.e., with respect to the Moon's surface (kilometers per second) (Fig. 6).

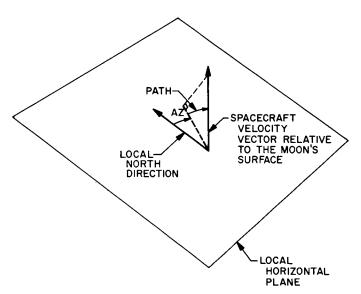

Fig. 6. Definition of path and azimuth angles

PTH-the angle between the Moon-fixed velocity vector and the local horizontal plane, positive upward (degrees) (see Fig. 6).

AZ—the azimuth direction of the projection of the Moon-fixed velocity vector into the local horizontal plane referenced to the local north direction, positive east of north (degrees) (see Fig. 6).

#### 3. Photo Data

The parameters in this sub-block are a function of both photograph number and position within the photograph. For this reason, several points within the frame format are specified, and parameter values are derived for each of these points. The points within each camera format

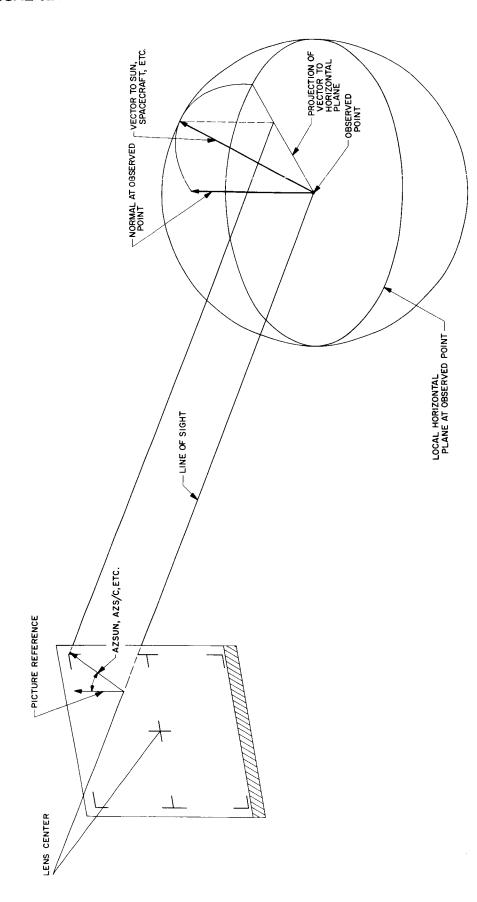

Fig. 7. Definition of azimuth directions

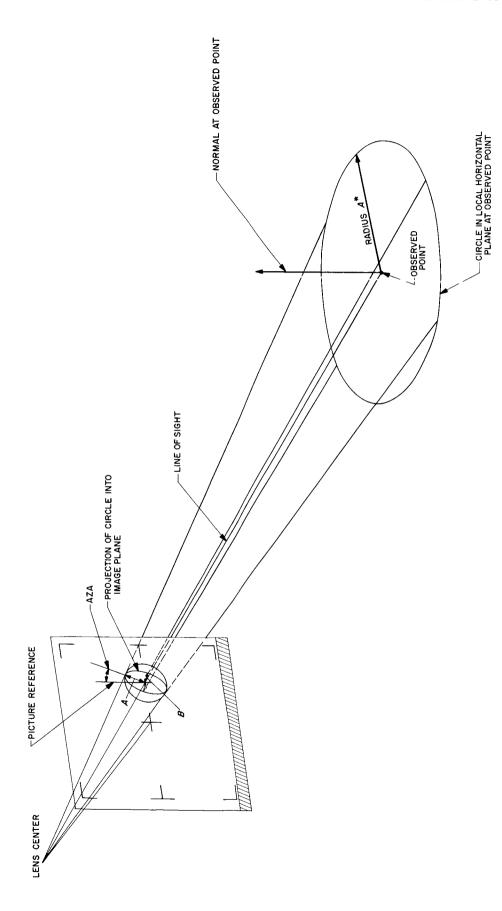

Fig. 8. Mapping of a circle into image plane

are taken at the reticle locations. Figures 3 and 4 identify the point number associated with each reticle of the Ranger VII cameras. In some cases, data are not derived for all reticles. Note also that the number 1 is not used to identify the reticles; this number is assigned to the velocity vector and, when it appears in the table, the velocity vector is within or near the field of view of the camera. The specification of this point, then, locates the point of zero image motion within the frame.

The parameters for which calculations are made at each picture point are described below. In all that follows, a spherical Moon with radius equal to that of the impact location is assumed.

The user is cautioned that angles are not preserved in the rectification of photographs. Thus, the angular values given in these tables are valid only for the unrectified *Ranger* pictures.

PT—the point number or reticle for which the calculations are made (see Figs. 3 and 4).

LAT, LON—the surface point selenocentric latitude—longitude coordinates covered by the reticle (degrees), hereafter referred to as the *observed surface point*.

RANGE—the distance from the camera to the observed surface point (kilometers).

AZ S/C—the picture-plane azimuth angle to the spacecraft, with respect to the picture reference and positive clockwise (degrees). This azimuth is found by obtaining the projection of the observed-surface-point-to-spacecraft vector into the local horizontal plane, and then mapping the projection into the picture or image plane (Fig. 7).

AZN—the picture-plane azimuth angle to true lunar north, with respect to the picture reference and positive clockwise (degrees). This azimuth is found by obtaining the projection of the lunar-center-to-north-pole vector into the local horizontal plane and then mapping the projection into the picture plane.

AZSUN—the picture-plane azimuth angle to the Sun, with respect to the picture reference and positive clockwise (degrees). This azimuth is found by obtaining the projection of the lunar-center-to-Sun vector into the local horizontal plane and then mapping the projection into the picture plane (see Fig. 7).

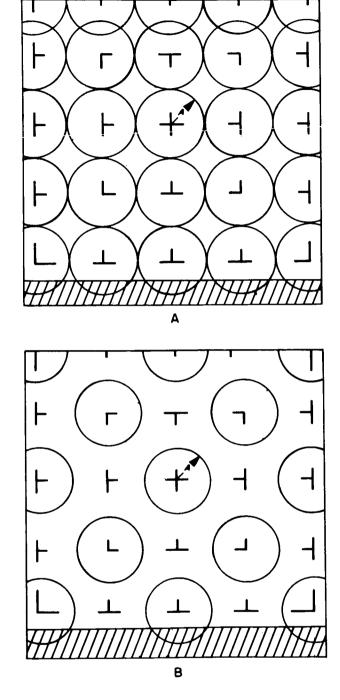

Fig. 9. Possible loci of semimajor axes of length A, resulting from mapping of surface circle with radius A\*

The following quantities describe the "skewness" of the photographs. In particular, these quantities detail the manner in which a circle on the surface, centered at the observed surface point, is mapped into an ellipse in the picture plane (Fig. 8). AZA—the picture-plane azimuth angle to the major axis of the ellipse resulting from the mapping of a circle on the surface into the picture plane, with respect to the picture reference and positive clockwise (degrees).

 $A^*$ —the radius of the circle on the surface that, upon being mapped into the picture plane, results in an ellipse of semimajor axis A ( $A^*$  in kilometers). In the case of the Ranger A and B cameras, the picture ellipse dimension A (Fig. 9) is specified as one-half the distance to the adjacent reticle. In the P cameras, the dimension A is related to the "base dimension"

sion" d as defined in Fig. 10. In Figs. 9 and 10, circles of radius A are circumscribed about each reticle for which data are derived. These circles indicate the locus of end points to which the semimajor axis of the ellipse resulting from imaging the surface circle of radius  $A^*$  will map.

B/A—the ratio of the semiminor to the semimajor axis of the ellipse resulting from the mapping of a circle on the surface into the picture plane.

The following quantities are useful for reproducing the photometric geometry and for photometric-brightness-to-slope conversions.

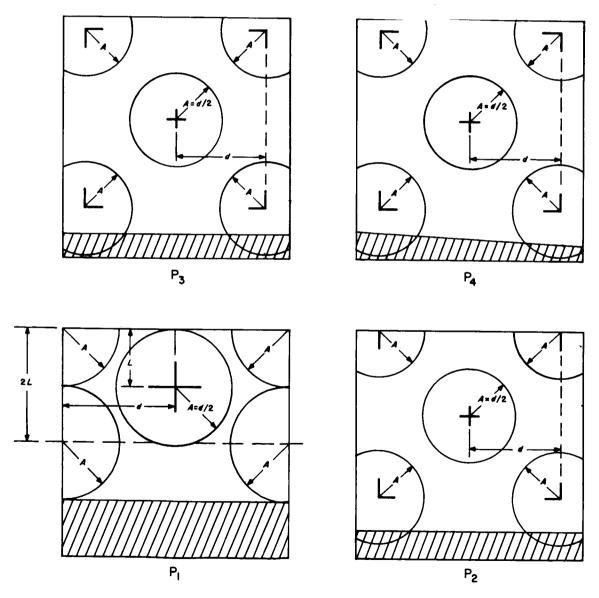

Fig. 10. Definition of base dimension d and possible loci of semimajor axes of length A, resulting from mapping of surface circle with radius A\*

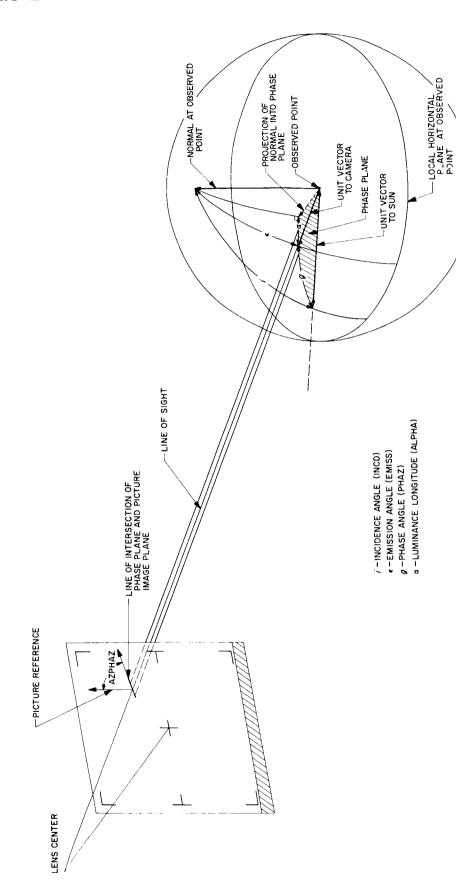

Fig. 11. Definition of AZPHAZ and photometric angles

AZPHAZ—the picture-plane azimuth angle to the phase plane, with respect to the picture reference and positive clockwise (degrees). This azimuth represents the line of intersection of the plane containing the phase angle (i.e., the phase plane) and the picture image plane. This is the only direction in which the picture may be scanned to derive exact elevation data when the two-angle lunar photometric function (Refs. 2 and 3) is used (Fig. 11).

INCD—the light incidence angle (degrees); i.e., the angle formed by the local normal (assuming a spherical Moon) and the vector from the observed surface point to the Sun.

PHAZ—the phase angle (degrees); i.e., the angle formed by the vector from the surface point to the Sun and the vector from the surface point to the camera.

EMISS—the emission angle (degrees); i.e., the angle formed by the local normal (assuming a spherical Moon) and the vector from the surface point to the camera.

ALPHA—the luminance longitude angle (degrees). This angle is the projection of the emission angle into the phase plane, with a sign convention applied. The angle is negative if it overlaps the phase angle and positive otherwise. The lunar photometric function is commonly written as a function of this angle and the phase angle.

The final two parameters of the table are used to provide a separate scaling technique from that of the surface circle mapping.

SCALE and PT to PT-the surface arc distance between the two points listed (kilometers).
